Coronavirus disease 2019 (COVID-19) vaccines have shown excellent safety profiles. The most common short-term side effects are injection site reactions, fever, fatigue, and headache, while severe adverse reactions have rarely been reported [1]. However, since mass-scale vaccination began, several immune-mediated reactions (including myocarditis and de novo or relapsed glomerulonephritis [GN]) have been reported [1]. COVID-19 vaccines have also been reported to induce T-cell activation [2]. In this regard, the occurrence of kidney disease following administration of a COVID-19 vaccine can be related to the T-cell–mediated immune response it generates to viral messenger RNA (mRNA), which can trigger podocyte injury [2]. Herein, we report a case of focal segmental glomerulosclerosis (FSGS) with segmental lobular collapse and podocyte proliferation following vaccination with the first dose of the Pfizer-BioNTech COVID-19 vaccine that mimicked the cellular lesions of FSGS.

A previously healthy 29-year-old man visited our hospital with complaints of edema and decreased urine output that had occurred 7 days previously. He had received a COVID-19 vaccine 2 weeks prior (Fig. 1). He had also undergone a health checkup 3 months before the visit, including urinalysis and renal function testing, which showed no abnormalities.

Upon physical examination, the patient was afebrile with a blood pressure of 140/80 mmHg, and there was noticeable edema. He had gained 10 kg (from 83 kg to 93 kg) within 1 week. Urinalysis showed the following results: protein, 4+; glucose, negative; red blood cells (RBCs), 10 to 19 per high-power field; and white blood cell (WBC) count, 1 to 4 per high-power field. Further evaluation showed WBC count, 6,800/mm$^3$; hemoglobin, 15.6 g/dL; platelet count, 277,000/mm$^3$; serum creatinine, 1.24 mg/dL; total protein, 4.7 g/dL; albumin, 2.5 g/dL; total cholesterol, 351 mg/dL; spot urine protein-to-creatinine ratio, 6.12 g/g; serum kappa-to-lambda light chain ratio, 0.79; serum complement C3, 144 mg/dL; and serum complement C4, 65 mg/dL. Additionally, the patient had negative serologic testing results for hepatitis B, hepatitis C, human immunodeficiency virus, anti-glomerular basement membrane antibody, rheumatoid factor, fluorescent antinuclear antibody, anti-neutrophil cytoplasmic antibody, anti-phospholipase A2 receptor-immunoglobulin G, and lupus anticoagulant. The screening test for COVID-19 was also negative.

A kidney biopsy was performed 31 days after the patient received his COVID-19 vaccination. Under light microscopy, the glomeruli were diffusely enlarged and hypercellular.
into the mesangium. Of the 20 glomeruli submitted, one (5.0%) exhibited FSGS with overlying podocyte proliferation (Fig. 2A). Electron microscopy revealed aggregates of RBCs in the capillary lumen with platelets and fibrin fibrils attached, which was suggestive of imminent microthrombus formation. The foot processes of the podocytes were diffusely effaced (Fig. 2B).

Based on these findings, we initiated treatment for FSGS with prednisolone (1 mg/kg daily), diuretics, angiotensin receptor blocker, and statin. Ten weeks after steroid treatment, the patient had no appreciable symptoms, and his laboratory results had normalized (serum albumin, 4.4 g/dL and creatinine, 1.03 mg/dL). The urine protein-to-creatinine ratio was 0.10 g/g.

Most cases of GN following COVID-19 vaccine have been associated with administration of an mRNA vaccine [1]. Foreign mRNA can induce strong innate and adaptive immune responses [2,3]. Among these responses, the T-cell response provokes swift production of cytokines (such as interferon-gamma, tumor necrosis factor-alpha, and interleukin-2), which could trigger podocytopathies and GN [3].

To the best of our knowledge, this is the first report of de novo FSGS following COVID-19 mRNA vaccine. Although we could not demonstrate definitive causality, we believe that the FSGS in this case might have been caused by a COVID-19 mRNA vaccine for the following reasons. First, a healthy patient suddenly developed nephrotic syndrome 7 days after vaccination. The onset of disease at this time point was compatible with that mentioned in previous reports of COVID-19 mRNA vaccine triggering enhanced T follicular helper cell (Tfh) responses that peak 7 days after vaccination [2]. The mRNA vaccine-induced Tfh population and the associated cytokine system in susceptible patients can promote podocyte injury [2]. Second, previous reports [4,5] have shown the development of recurrent FSGS lesions as early as 1 to 2 months after renal transplantation, which further support that the sclerotic lesions visible in this case could be a consequence of rapidly progressive podocytopathy triggered by a COVID-19 mRNA vaccine. Third, many viral infections, including COVID-19, are well-known triggers for glomerular lesions and stimulate the onset of de novo and relapsing GN [2,6]. Because mRNA it-
self can be highly immunogenic, like an intact mRNA virus, COVID-19 mRNA vaccine-induced immune responses are analogous to COVID-19 virus-induced immune responses, both resulting in de novo and relapsing GN \cite{2,7}. It is noteworthy that the FSGS in our case was a non-collapsing cellular variant, while COVID-19-induced FSGS is most commonly the collapsing type \cite{7}.

Our patient with no apparent underlying disease presented with FSGS after vaccination. We also acknowledge that increased patient awareness of symptoms after vaccination might lead to the recognition of previously undiagnosed kidney disease \cite{2}. Although these associations do not prove causation, we believe that the abrupt onset of nephrotic syndrome following vaccination and the consistent time course of events indicate a direct role of mRNA vaccines \cite{2,6}. Therefore, physicians should be aware of the possibility of FSGS development associated with vaccination. Further studies are needed to verify the cause of FSGS related to administration of COVID-19 vaccine and to study the risk factors for FSGS after COVID-19 immunization.
